

Benchmark dose contours for bivariate exposures :  
application to maternal drinking patterns and  
childhood cognition

**Session: CPS16**  
**Experimental Design and Clinical Trials**

Jacobson, Joseph Jacobson  
Monday 6 October, 16:00-17:00

# Motivation

- **Fetal Alcohol Syndrome (FAS):** craniofacial dysmorphology, growth restriction, neurobehavioral dysfunction
- **Partial FAS:** dysmorphology + neurobehavioral dysfunction
- **Alcohol-Related Neurotoxic Disorder (ARND):** cognitive/behavioral impairment without dysmorphology (most prevalent)

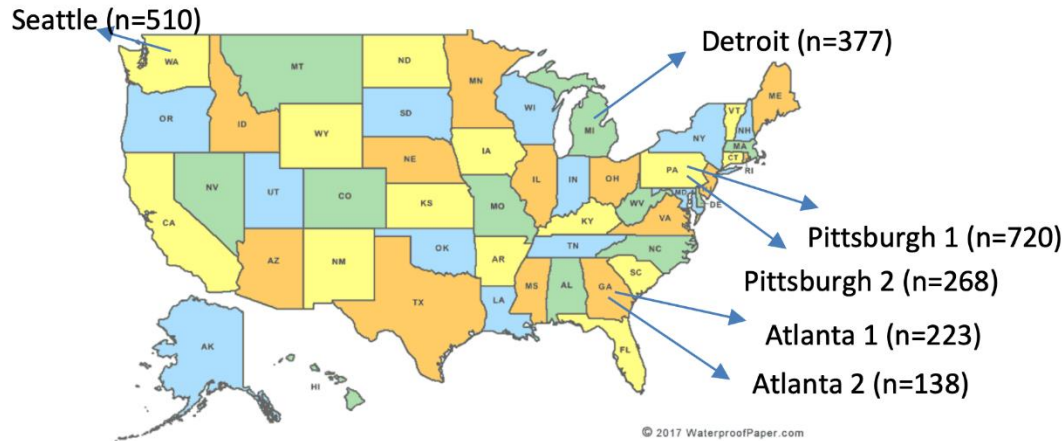

# Diagnostic Challenges

- FASD not officially recognized in DSM-5
- ND-PAE introduced (condition for further study)
- Criteria lower than earlier cutoffs and NIAAA binge definition
- Screening & referral recommended, but underdiagnosis persists due to lack of dose–response guidance

# NIH Study

- Six longitudinal U.S. cohorts combined (N = 2226 mother–child pairs).
- Offspring followed from infancy to childhood.
- Outcomes: IQ + 4 cognitive domains (learning, memory, exec. function, academic achievement).

# Evidence on Prenatal Alcohol Exposure and Outcomes

- Jacobson et al. (2021) meta-analysis (N>2000, 6 cohorts)
  - Modest, robust effects of PAE on cognitive function (after adjustment)
- Nonlinear dose-response suggested by semi-parametric models:
  - Little/no effect at low exposure
  - Stronger effects at moderate/heavy levels (Jacobson & Jacobson 1994; Goldschmidt 1996)
- Animal studies: acute high-dose exposure more damaging than gradual intake (Bonthius 1990; Goodlett 1987)

# Why Benchmark Dose?

- Evidence shows nonlinear effects of prenatal alcohol exposure.
- Traditional cutoffs (e.g., binge/no binge) may miss gradual risks.
- Need a data-driven threshold:
  - Captures low-level risk often overlooked.
  - Provides transparent, reproducible cutoff for public health and clinical guidelines.

# Benchmark Dose (BMD)

- BMD: exposure level at which risk of adverse response increases by a chosen benchmark response (BMR).
- Traditionally: estimated for a single exposure.
- Public health use: lower confidence limit (BMDL) applied for safety margins.

# Limitations of current methods

- Most methods univariate.
- Real exposures often multidimensional (e.g. dose/occasion & frequency).
- Need: BMD surfaces/contours for bivariate exposures.

## Our framework

- Generalized additive models (GAMs):  
Flexible, nonlinear dose-response surfaces for alcohol dose/occasion  $\times$  drinking frequency
- Confounder adjustment via propensity scores:  
Account for potential sociodemographic and risk factor confounding
- Extension to bivariate BMD analysis:  
Define BMD contours at specified risk increase  
Parametric bootstrap for BMDL confidence contours
- R package *semibmd*

# Application: Prenatal Alcohol Exposure

- 2226 children across 6 cohorts
- Exposure metrics:
  - Dose per drinking occasion
  - Drinking frequency (days/month)
- Outcome: Composite cognitive function (standardized)
- Method: Bivariate GAM  $\rightarrow$  flexible nonlinear dose-response

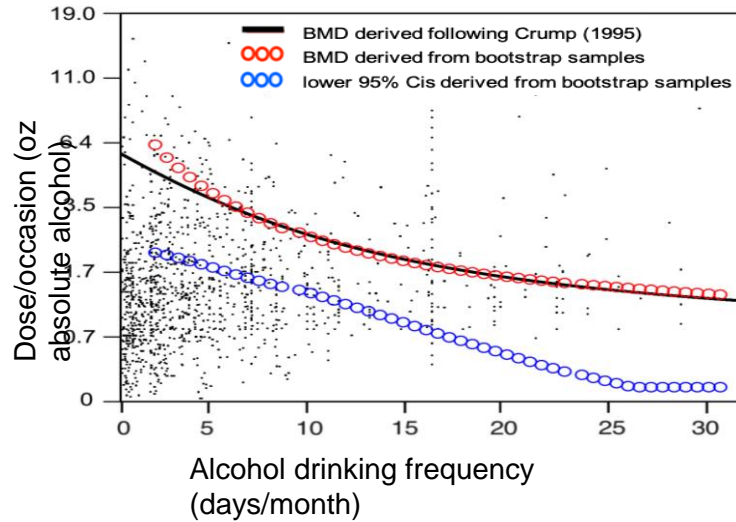

# Benchmark Dose (BMD) Approach

- Defines exposure that increases impairment risk by ~1%
- Cutoffs:
  - Intellectual disability:  $IQ < 70$
  - Poor intellectual function:  $IQ \approx 77$
- BMDL: lower confidence bound for policy thresholds

# Application: Prenatal Alcohol Exposure

Intellectual disability

Poor intellectual function

# Discussion

- Developed bivariate BMD analysis framework.
- Provides clinically interpretable exposure thresholds.
- Flexible, extends to more exposures with modification.
- R implementation available: semibmd.

QUESTIONS?

THANK YOU.
